

Figure 1: Schematic of the epidemic-control modelling workflow. Weekly case counts, mobility traces and vaccination coverage are assembled for the study city and, in preprocessing, cleaned and aligned onto a common weekly grid. Transmission parameters are estimated by fitting a compartmental model to the aligned data (calibration); if the fit residual is unacceptable the model structure or the priors are revised and calibration is repeated, and once the fit is accepted the calibrated model is projected forward under three policies (no intervention, a vaccination campaign, and school closure). The three projections are compared and ranked, and the ranking is written up as the paper’s recommendation.
