

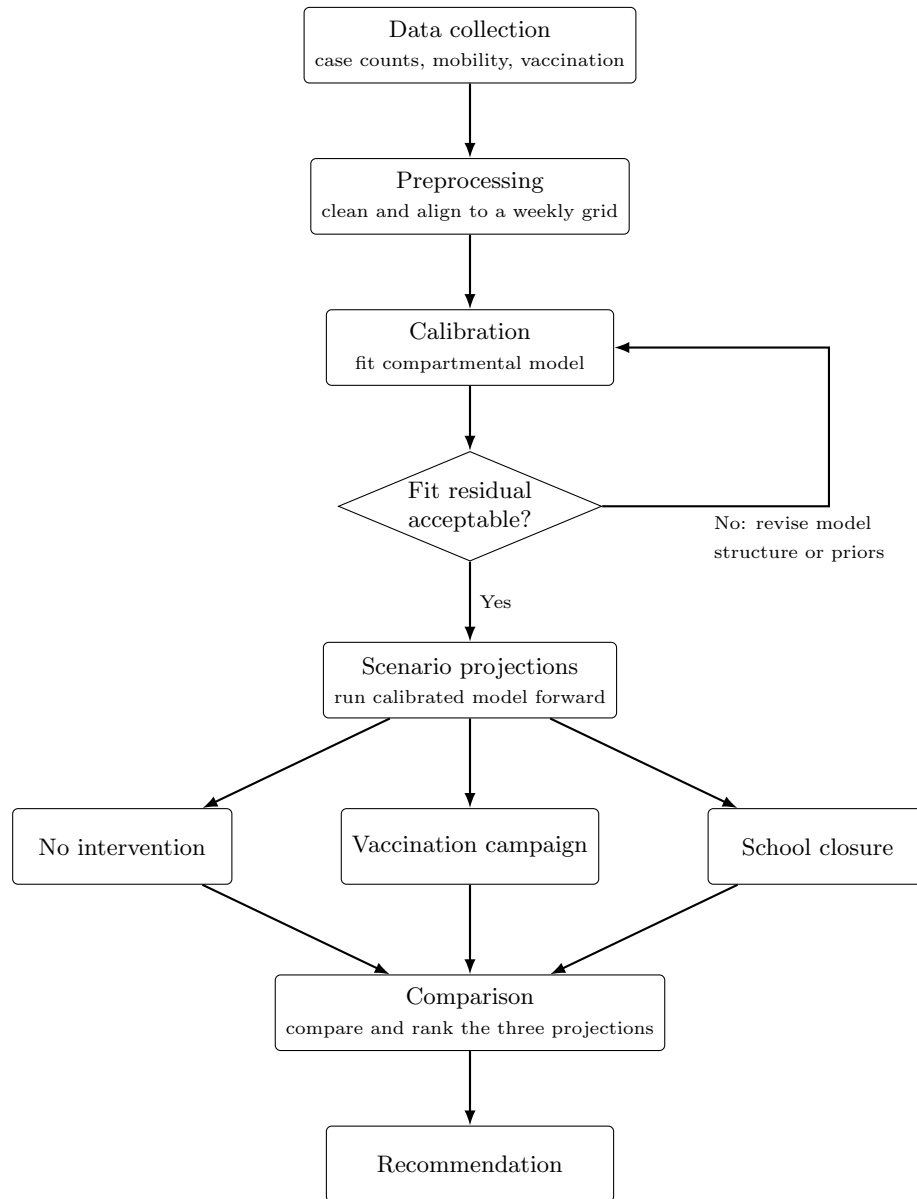

Figure 1: Modelling workflow. Weekly case counts, mobility traces and vaccination coverage for the study city are collected and, during preprocessing, cleaned and aligned onto a common weekly grid. Transmission parameters are then estimated by fitting a compartmental model to the aligned data. If the fit residual is not acceptable, the model structure or the priors are revised and calibration is repeated (this loop may run more than once). Once the fit is acceptable, the calibrated model is projected forward under three alternative policies — no intervention, a vaccination campaign, and school closure — and the three projections are compared and ranked to produce the recommendation written into the paper.
